Minimum spanning tree with conflicting edge pairs: a Branch-and-Cut approach

Received: date / Accepted: date

Abstract In this paper, we show a Branch-and-Cut approach to solve the Minimum Spanning Tree problem with conflicting edge pairs. This is a NP-hard variant of the classical Minimum Spanning Tree problem, in which there are mutually exclusive edges. We introduce a new set of valid inequalities for the problem, based on the properties of its feasible solutions, and we develop a Branch-and-Cut algorithm based on them. Computational tests are performed both on benchmark instances coming from the literature and on some newly proposed ones. Results show that our approach outperforms a previous Branch-and-Cut algorithm proposed for the same problem.

Keywords minimum spanning tree \cdot conflicting edges \cdot Branch-and-Cut

1 Introduction

The minimum spanning tree problem with conflicting edge pairs (MSTC) is a very recent variant of the classical minimum spanning tree (MST) problem. Given a connected, undirected and edge-weighted graph, as well as a set of edges pairs in conflict with each other, a feasible MSTC solution is a spanning tree without conflicts whose total weight is minimal, i.e., a minimum spanning tree containing at most an edge for each pair in the conflict set.

Variants of the same type (that is, with the addition of conflicts) have already been studied for other classic problems, such as the knapsack problem [7], the maximum flow problem [8], the bin packing problem [9] and the minimum cost perfect matching [5].

The specific variant concerning the minimum spanning tree problem was studied for the first time by Darmann et al. [2] in 2009. The authors showed that the problem, in general, is not solvable in polynomial time. In particular,

Department of Mathematics, University of Salerno

E-mail: {fcarrabs,raffaele,rpentangelo,araiconi}@unisa.it

there exist two cases in which the problem becomes polynomially solvable: when all pairs of edges in conflict are disjoint ([2], [3]) or when the transitive property holds for the set of such pairs [11]. In [11], the authors presented several meta-heuristic approaches to solve the MSTC problem, while the first authors to face the problem through an exact approach have been Samer and Urrutia in [10]. They presented a mathematical model for the MSTC problem, as well as two sets of valid inequalities. In order to introduce these new sets of valid inequalities, the authors gave an equivalent definition of the problem by defining the concept of *conflict graph*, that we will resume in Section 2.

In this paper, we propose a Branch-and-Cut approach for the MSTC, and test its effectiveness and performance on a set of instances originally proposed in [11]. We compared these results with those obtained by the exact algorithm presented in [10], that was tested on the same dataset. The comparison showed that our algorithm outperformed the previous one in all cases except one, and was able to find one additional optimal solution. Furthermore, we also test our approach on a new, wider set of instances that we generated.

The paper is organized as follows. A formal description of the problem, together with the needed definitions and notations, are presented in Section 2. In Section 3, a mathematical formulation for the MSTC is provided. Moreover our novel valid inequalities, together with the ones used in [10], are presented. The proposed Branch-and-Cut algorithm is described in Section 4, while computational results are presented in Section 5. Finally, Section 6 contains our conclusions.

2 Notations and problem definition

Let G = (V, E) be an undirected, edge weighted graph, where V is the set of n vertices and E is the set of m edges. We denote by w_e the weight associated to the edge $e \in E$. For a given subset $S \subseteq V$, let E(S) be the set of the edges with both endpoints in S. Furthermore, let P be a set of edge pairs of E, called *conflict set*, defined as follows:

$$P = \{\{e_i, e_j\} : e_i, e_j \in E, e_i \text{ is in conflict with } e_j\}.$$

For each $e_i \in E$, we indicate with $\chi(e_i)$ the set of edges that are in conflict with it.

The MSTC problem consists of finding the minimum spanning tree $T = (V_T, E_T)$ of G such that its edges are conflict free, i.e.

$$\forall e_i, e_j \in E_T, \{e_i, e_j\} \notin P.$$

We now resume the concept of conflict graph G' = (E, P), originally presented in [10]. G' contains a node for each edge E of G, and two nodes e_i, e_j are connected in G' if and only if $\{e_i, e_j\} \in P$.

Figure 1 shows an example of graph G and the related conflict graph G'. We can note that, for instance, $\{e_1, e_3, e_5, e_6, e_8\}$ is a feasible MST solution being a spanning tree of G, but it is not feasible for the MSTC since $\{e_1, e_5\} \in P$. On

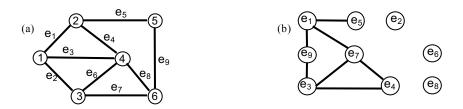

Fig. 1: (a) An example of graph G with |V| = 6, |E| = 9 and conflict set $P = \{\{e_1, e_5\}, \{e_1, e_7\}, \{e_1, e_9\}, \{e_3, e_4\}, \{e_3, e_7\}, \{e_3, e_9\}, \{e_4, e_7\}\}$ (|P| = 7). (b) The related conflict graph G' = (E, P), where each node corresponds to an edge of G and each edge corresponds to a pair in P.

the other hand, $\{e_2, e_4, e_5, e_6, e_9\}$ is a conflict free spanning tree and therefore it is a feasible MSTC solution.

3 Basic Mathematical Model

In this section we present a mathematical model for the MSTC problem, based on a traditional Subtour Elimination formulation for the MST with the additional constraints to avoid the conflicts. This model was also considered in [10]. The formulation only uses a type of decision variables x_e associated with the edges of G, with the following meaning:

$$x_e = \begin{cases} 1 & \text{if } e \text{ is selected,} \\ 0 & \text{otherwise.} \end{cases}$$

The mathematical programming formulation of the MSTC is the following one.

$$(\mathbf{ILP}) \quad \min \sum_{e \in E} w_e x_e \tag{1}$$

s.t.

$$\sum_{e \in E} x_e = |V| - 1,\tag{2}$$

$$\sum_{e \in E(S)} x_e \le |S| - 1, \qquad \forall S \subseteq V, S \ne \emptyset, \tag{3}$$

 $x_{e_i} + x_{e_j} \le 1, \qquad \forall \{e_i, e_j\} \in P, \tag{4}$

$$x_e \in \{0, 1\}, \qquad \forall e \in E. \tag{5}$$

The objective function (1) minimizes the weight of the spanning tree. Constraint (2) imposes the selection of n-1 edges (recall that |V| = n) while

3

Constraints (3) are the classical subtour elimination constraints. Finally, Constraints (4) ensure that two edges in conflict cannot be simultaneously selected in the solution while constraints (5) are the integrality constraints.

3.1 Valid inequalities

In this section we present three classes of valid inequalities for the MSTC that we used to design a Branch-and-Cut approach for this problem. The first class, named *degree-cut* inequalities, ensure that there are not isolated vertices in the solution; we use them to enforce the Subtour Elimination model. The second one, the *conflict-cycle* inequalities combine the request of avoiding both cycles and conflicts and represent our main contribution. Finally, the third class of inequalities are the well known *odd-cycle* inequalities that are derived from the conflict graph structure. In the following section we describe in details these valid inequalities.

3.1.1 The degree-cut inequalities

Since the solution of the MSTC is a spanning tree then for each node of V at least one incident edge is selected. For this reason, we add to our model the following valid inequalities:

$$\sum_{e \in \delta(v)} x_e \ge 1, \qquad \forall v \in V.$$
(6)

The constraints (6) state explicitly that the degree of any node into the solution must be greater than or equal to 1. These inequalities improve the relaxed solution value of ILP model. Indeed, by removing the constraints (3) from ILP model, the optimal solution is obtained by selecting the cheapest n-1 edges of the graph. This could lead to the presence of isolated nodes (i.e. with degree equal to zero) in the solution. The inequalities (6) prevent the construction of these type of solutions.

Since the number of inequalities (6) is equal to n, no separation procedures are applied but they are directly introduced into the ILP model as a priori constraints. Obviously, these constraints are not necessary to represent the solutions space but, in our experiments, they speed up the convergence of our Branch-and-Cut.

3.1.2 Conflict-cycle inequalities

The conflict-cycle inequalities are a stronger version of the subtour elimination constraints obtained by exploiting the conflicts among the edges.

Let ζ be a set of edges that generate a cycle in G, and let us suppose that two of these edges are in conflict with another edge e_c that does not belong to ζ . Then, in any feasible solutions of MSTC, the number of edges of $\zeta \cup \{e_c\}$

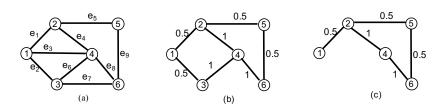

Fig. 2: (a) The input graph G. (b) A feasible solution that satisfies constraints (2)-(4) and the inequalities $0 \le x_e \le 1, \forall e \in E$. (c) Considering the cycle $\zeta = \{e_4, e_5, e_9, e_8\}$ in the solution (b) and edge e_1 in conflict with e_5 and e_9 , the related constraint (7) is violated.

must be lower than or equal to $|\zeta| - 1$. The following theorem proves that these inequalities are valid for the MSTC.

Theorem 1 Let ζ be a cycle of G and let e_c be an edge outside this cycle that is in conflict with two edges of ζ . Then the constraint

$$\sum_{e_i \in \zeta} x_{e_i} + x_{e_c} \le |\zeta| - 1,\tag{7}$$

is a valid inequality for the MSTC problem.

Proof By contradiction, let us suppose that in a feasible solution of MSTC we have:

$$\sum_{e_{i'} \in \zeta'} x_{e_{i'}} + x_{e_g} > |\zeta'| - 1,$$

where $\zeta' \subseteq E$ is a cycle of G, $e_{j'}, e_{k'} \in \zeta'$, $e_g \in E \setminus \zeta'$, and $e_{j'}, e_{k'} \in \chi(e_g)$. We have to consider the following two cases:

- If $x_{e_g} = 0$ then $\sum_{e_{i'} \in \zeta'} x_{e_{i'}} > |\zeta'| - 1$. However, this last condition violates Constraints (3). A contradiction.

- if $x_{e_g} = 1$ then

$$\sum_{e_{i'} \in \zeta'} x_{e_{i'}} + 1 > |\zeta'| - 1 \quad \Rightarrow \quad \sum_{e_{i'} \in \zeta'} x_{e_{i'}} > |\zeta'| - 2.$$

Due to this last condition at least one of variables $x_{e_{j'}}$ and $x_{e_{k'}}$ must be equal to 1, thereby violating the Constraints (4).

Inequalities of type (7) are called conflict-cycle inequalities.

In Figure 2 an example of how the inequalities (7) work is shown. Figure 2(a) is the initial graph. Notice that the solution in Figure 2(b) satisfies

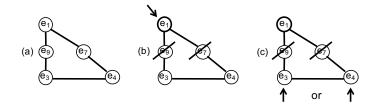

Fig. 3: (a) An odd-cycle of length 5 in the conflict graph G' in Figure 1. (b) If we choose e_1 , it is not possible to choose e_5 and e_9 . (c) At this point, only one between e_3 and e_4 can be part of a MSTC solution.

the classical subtour elimination constraints, while it is cut off by inequalities (7). Indeed, considering the cycle $\zeta = \{e_4, e_5, e_9, e_8\}$ (Figure 2(c)), we note that e_5 and e_9 belong to $\chi(e_1)$ (see Fig. 1).

3.1.3 Odd-Cycle inequalities

Another set of valid inequalities for the MSTC are the well-known odd-cycle inequalities. These inequalities are based on the conflict graph G' described in Section 2. Each vertex of G' is associated to an edge of G and two nodes are connected if the corresponding edges of G are in conflict. This means that the selection of two connected vertices in G' is equivalent to select two edges in conflict in G. For this reason, given a cycle ζ' of G', having an odd number k of edges, it is easy to see that it is possible to select at most $\frac{k-1}{2}$ vertices of the cycle (that is, edges of G) without violating the conflict constraints. Formally,

$$\sum_{e \in C'} x_e \le \frac{|C'| - 1}{2}, \qquad \forall C' \subseteq E \quad odd - cycle \quad in \quad G'$$
(8)

In Figure 3 we show that, given an odd cycle of length 5 in the conflict graph of the example in Figure 1, the maximum number of edges that can be chosen is $\frac{5-1}{2} = 2$.

A Branch-and-Cut approach based on the ILP model and using, among the others, the odd-cycle inequalities was presented in [10]. In the computational test section we will carry out a comparison between our Branch-and-Cut approach and theirs.

4 Branch-and-Cut

In this section, we outline the main ingredients of our Branch-and-Cut algorithm for the optimal MSTC solution as well as the separation procedures for the valid inequalities described in previous section. To obtain upper bounds that help pruning the search tree, we use the genetic algorithm proposed in [1]. However, it is known that even finding a feasible MSTC solution is NP-hard; furthermore, for the instances proposed in [10] that we used in our computational tests, a feasible solution is not guaranteed to exist. For these reasons, there are several instances where these upper bounds are not available. Furthermore, we did not implement a primal heuristic; indeed, its execution would not benefit in the infeasible cases, and in the other ones it would not guarantee the individuation of many solutions, and hence a positive impact on the computational times of BC.

7

4.1 Initial relaxation

The initial relaxation of ILP, named $\mathscr{R}(ILP)$, is composed by constraints (2),(4),(6) and the inequalities $0 \le x_e \le 1$.

4.2 Separation procedures

The odd-cycle inequalities are separated by using the exact algorithm proposed in [4] while the subtour elimination constraints are separated by using the exact algorithm presented in [6].

In the following, we describe our procedure to separate conflict-cycle inequalities (7). Given a solution \bar{x} of $\mathscr{R}(ILP)$, we build a new graph G = (V, E)where $\tilde{E} = \{e = (i, j) \in E : \bar{x}_e > 0\}$. To each edge $\tilde{e} \in \tilde{E}$ the weight $w_{\tilde{e}} = 1 - \bar{x}_{\tilde{e}}$ is assigned. The conflict-cycle inequalities (7) are heuristically separated by using the graph \tilde{G} with the following procedure. Given any couple of nodes $\tilde{v}_1, \tilde{v}_2 \in V$ such that $(\tilde{v}_1, \tilde{v}_2) \in E$, we look for the shortest path between them in \tilde{G} which does not include the edge $(\tilde{v}_1, \tilde{v}_2)$. If such a path exists, we append $(\tilde{v}_1, \tilde{v}_2)$ to it, obtaining a cycle $\zeta \subseteq E$. To individuate a violated inequality, we look for an edge $\tilde{e}_3 \in \chi(\tilde{e}_1) \cap \chi(\tilde{e}_2) \setminus \zeta$ where $\tilde{e}_1, \tilde{e}_2 \in \zeta$ and such that $\sum_{\tilde{e}\in\tilde{\zeta}} \bar{x}_{\tilde{e}} + \bar{x}_{\tilde{e}_3} > |\tilde{\zeta}| - 1$; hence we look for all possible edges of this type and all the violated inequalities are introduced in the model. Note that if $\sum_{\tilde{e}\in\tilde{\zeta}} \bar{x}_{\tilde{e}} + 1 \leq |\tilde{\zeta}| - 1$, it is impossible to find violated inequalities of the type (7), hence we don't look for them in this case. Furthermore, we decided to use an additional tolerance parameter $\epsilon_c \geq 0$, meaning that we only consider violated inequalities if $\sum_{\tilde{e}\in\tilde{\zeta}} \bar{x}_{\tilde{e}} + \bar{x}_{\tilde{e}_3} > |\tilde{\zeta}| - 1 + \epsilon_c$. The computational complexity of this algorithm is $O(m^2 logn)$. In fact the individuation of a shortest path requires $|\tilde{E}|log|V|$ and it is invoked for each edge in \tilde{E} . We use an m x m binary matrix to state in O(1) that two edges are in conflict.

Note that the separation procedure for the subtour elimination constraints cannot be used for inequalities (7), because it is not sufficient to individuate the set of vertices S that generate a cycle. We need to know what are the edges of the cycle to separate the conflict-cycle inequalities.

4.3 Cutting plane phase

At each iteration of the cutting-plane algorithm:

- if the variables in the LP solution are all integer, the subtour elimination constraints (3) are heuristically separated through a DFS procedure;
- otherwise, the following separation procedures are used:
 - 1. Exact separation procedure [6] for the subtour elimination constraints (3).
 - 2. Heuristic algorithm for separating the conflict-cycle inequalities (7) with $\epsilon_c = 0.1$.
 - 3. Exact algorithm for separating the odd-cycle inequalities (8) only at the root node.

If all separation procedures fail to find violated inequalities or a tailing-off criterium is met, we branch on variables using the default parameters of CPLEX. The tailing-off is applied when the improvement in the upper bound is less than 10^{-5} in five consecutive iterations.

To keep the size of the LP as small as possible, in each node of the search tree we never add more than 50 valid inequalities. The value of this parameter was chosen after a preliminary tuning phase.

5 Computational results

In this section we present the computational results of the tests we made in order to evaluate the performance of our Branch-and-Cut algorithm (from now on called BC). The algorithm was coded in C++ on an OSX platform (iMac, mid 2011), running on an Intel(R) Core(TM) i7-2600 CPU 3.40GHz (family 6, model 42, stepping 7) with 8 GB of RAM, equipped with the IBM ILOG CPLEX 12.6.1 solver (single thread mode).

In Section 5.1 we evaluate the performances of BC, also in comparison with the approach presented in [10], on their proposed instances. We further evaluate the performances of our algorithm on a new set of instances in Section 5.2. An analysis of the impact of the proposed valid inequalities is provided in Section 5.3.

5.1 BC performance analysis and comparison on benchmark instances

We compared the results of BC with the Branch-and-Cut algorithm (from now on called SU) proposed in [10]. Following [10], for all the experiments we considered a time limit equal to 5000 seconds. Furthermore, we considered a memory limit set to 3 GB. In this previous work, the authors propose a preprocessing procedure to simplify the instances before solving them. They divided the instances in two subsets, namely type 1 and type 2. Instances belonging to type 2 resulted to be very easy to solve after the preprocessing phase. Indeed, the authors do not present results about the SU performances on these instances, since they state that after this preprocessing (taking up to

Table 1: Comparison between the solution values of SU and BC algorithms.

18 seconds) all instances of this group were solved in negligible time. On these same instances, the genetic algorithm that we used to initialize our method always found (in up to 26 seconds) solutions that were very quickly certified to be optimal by BC. For these reasons, we compare our results only on the harder type 1 instances. We want to remark that we did not apply any preprocessing before solving them with BC. As will be shown, despite this, we obtained better results in all cases except one. This result, in our opinion, emphasizes the effectiveness of our algorithm.

Table 1 reports the results of the comparison between BC and SU.

The first four columns of the table show the information concerning the instance: a numerical identifier (id), the number of nodes (n), of edges (m) and of conflict pairs (p). The next two columns report the lower (LB) and upper (UB) bounds found by SU. When the lower and the upper bounds coincide, i.e. an optimal solution is found, the optimal value is reported between the LB and UB columns. When a "-" is reported, no feasible solution has been found. Finally, the last three columns report the lower bound, the upper bound and the computational time (Time), in seconds, of BC. The bounds are shown in bold whenever the solution found by BC is better than the solution found by SU. In [10] the authors did not report the computational time spent by SU on these instances, and therefore we cannot carry out a precise comparison between the two Branch-and-Cut from this point of view.

The first 6 instances and instance $n^{\circ}8$ are solved optimally by both algorithms. The instance $n^{\circ}9$, instead, is solved to optimality by BC in 1239.4 seconds, while it was not solved by SU within 5000 seconds. Therefore, our algorithm provides a new optimal solution for this set of instances. Both the algorithms certify the infeasibility of instances $n^{\circ}15$, 20 and 23. For the remaining 12 instances, BC produces better lower bounds in all cases except one (instance $n^{\circ}21$).

With respect to the subset of instances that are not solved by BC and SU, both algorithms found upper bounds in the same 3 cases (instances n° 10, 13 and 16), and those found by BC are always better. It is worth noting the percentage gap value between the upper and the lower bounds in these cases. This value is computed as $100 \times \frac{UB-LB}{UB}$. On the instance n°10, the percentage gap is equal to 31.03% for SU and 16.66% for BC. On the instance n°13, it is equal to 11.11% for SU and 6.49% for BC. Finally, for the instance n°16, it is equal to 5.07% for SU and 2.84% for BC. That is, the percentage gap of BC for these instances is about half of the percentage gap of SU.

Regarding the performance, all the instances optimally solved by BC required less than 12 seconds, except for the instance $n^{\circ}9$ for which, as previously mentioned, about 1240 seconds were spent. To certify the infeasibility, BC required around 16 seconds on the instance $n^{\circ}15$, 2911 seconds on the instance $n^{\circ}20$ and 1820 seconds on the instance $n^{\circ}23$.

5.2 BC performance analysis on new instances

In order to further investigate the effectiveness and performance of BC, we generated a new set of benchmark instances. The number of nodes n in this new set ranges from 25 to 100, with incremental steps of size 25. The number of edges m is assigned according to the following density values: 0.2, 0.3, 0.4. A random integer weight chosen in the interval [10,30] is assigned to each edge. That is, a graph with density d has m = dn(n-1)/2 edges. This means that our instances are much denser than the previous ones, in which the highest density value is about 0.16.

Given m edges, we can generate at most $\binom{m}{2} = m(m-1)/2$ conflict pairs. The number of conflict pairs associated to each instance is equal to 1%, 4% and 7% of m(m-1)/2. We generated 5 different instances for each combination of parameters n, m and p. Thus, in total we generated 180 new instances. The combinations of these parameters allow us to determine which of them affects most the BC performances. It is also worth noting that the new instances were generated ensuring their feasibility, therefore there are no unfeasible instances as in the previous set.

We show the results on this new dataset in Tables 2 and 3. The meaning of id, n, m and p are the same as for Table 1. Under the s columns we report the value of a seed parameter that was used to generate different instances with the same parameter values. The column MST indicates the value of the minimum spanning tree without taking into account the conflict set P. The

Table 2: Computational results of BC on new instances: (a) n = 25, (b) n = 50

last three columns report, as in Table 1, the results of our approach (lower bound (LB) and upper bound (UB), or a value in between when an optimum is found) and the computational times in seconds.

We can see that all instances with n = 25 (Table 2(a)) are solved to optimality within 0.5 seconds, with 38 out of 45 of them requiring under 0.1 seconds. We can, however, start noticing a trend with respect to how parameters affect the complexity of the instances. Indeed, the 4 instances that required the most time to be solved all correspond to cases in which the number of conflict pairs is the highest, with respect to the other instances with the same number of edges. These cases correspond to instances n°36 (m = 60, p = 124), n°50 (m = 90, p = 281), n°65 and 66 (m = 120, p = 500), that are solved in 0.3, 0.5, 0.5 and 0.4 seconds, respectively.

The trend is confirmed for instances of all sizes. For n = 50 (Table 2(b)) we can observe that all instances with p equal or less than the 4% of $\binom{m}{2}$ are again solved optimally, with computational times growing up to 6.3 seconds for m = 245, 7.5 seconds for m = 367 and 13.8 seconds for m = 490. When p grows to the 7% of the maximum number of conflicts, the related instances result to be considerably more difficult to solve, since we reach a certified optimal solution only for 2 out of 15 of them, namely instances n°80 and 83, solved in 1938.69 and 25.7 seconds, respectively. In the other 13 cases, the gap between the returned lower and upper bounds are between 2% and 8%

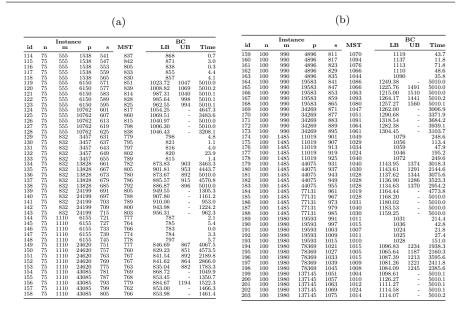

Table 3: Computational results of BC on new instances: (a) n = 75, (b) n = 100

for m = 245, between 3% and 8% for m = 367 and between 3% and 7% for m = 490.

When n = 75 (Table 3(a)) we are able to find optimal solutions for all the 15 instances with p equal to the 1% of $\binom{m}{2}$. Computational times in these cases grow up to 23.9 seconds once (instance n°132) and are lower than 5.5 seconds for the remaining 14 instances. None of the remaining 30 instances is solved to optimality. When p = 4% of $\binom{m}{2}$, we were always able to find both an upper and a lower bound, with gaps between 1% and 6% for m = 555, between 1% and 5% for m = 832 and between 2% and 6% for m = 1110. It can be noticed that in 3 out of 5 cases for m = 832 as well as in all 5 cases with m = 1110 the computational times are lower than the time limit, as in these cases it was the memory limit to be reached first. The instances with the p equal to the 7% of $\binom{m}{2}$ are again the hardest, since we were able to identify a lower bound only for one of them (instance n°156). Even in this case, the gap between upper and lower bound is considerably high, being equal to 26%. In 13 out of 15 cases we reached the memory limit.

Finally, we consider the results for instances with n = 100, reported in Table 3(b). Again, all instances with p = 1% of $\binom{m}{2}$ could be solved to optimality, within 71.8 seconds for m = 990, 249.6 seconds for m = 1485 and 214.4 seconds for m = 1980. None of the instances with p = 4% of $\binom{m}{2}$ was solved to optimality, and we were able to identify a lower bound for each of them except one (instance n°164). The gaps between lower and upper bounds are between 12% and 20% for m = 990, between 11% and 17% for m = 1485 and between 10% and 13% for m = 1980. The time limit was always reached

for the 5 instances with the smallest number of edges, while the memory limit was always reached in the remaining 10 cases. Finally, when p = 7% of $\binom{m}{2}$ we were never able to find an upper bound. The memory limit was reached for 6 of these instances, while the time limit was reached in the other 9 cases. With respect to the MST column, we note that for no instance of our new dataset the optimal solution coincides with this trivial lower bound.

13

To conclude we can note that, predictably, the factor that most affects the BC performances is the ratio between the number of edges and the number of conflict pairs. Indeed, as p grows with respect to m, it becomes more difficult to find feasible solutions. Between instances with the same number of nodes, increasing the number of edges while keeping constant this ratio have in many cases either marginal or unnoticeable effect on the performances. While increasing the number of nodes leads to harder instances, even the largest ones (with up to 100 nodes and 1980 edges) with the fewest number of conflict pairs could be solved to optimality within about 4 minutes.

5.3 Valid inequalities performance analysis

In this section we evaluate the impact of our valid inequalities on the effectiveness and performance of BC. To this end, we compare BC with a "basic" Branch-and-Cut algorithm composed by constraints (2)-(5) and (8). We will refer to this approach with the name "Basic" from now on. We carry on this comparison on the larger and more diverse set of instances that we introduced in this work. We recall that these instances are guaranteed to be feasible. In order to better assess the effectiveness of our new valid inequalities, we did not provide a starting solution for these tests. Furthermore, a 5000 seconds time limit was considered also for these tests.

The results of this comparison are reported in Table 4. The first column reports the instance id. The following eight columns report, for each of the two approaches, the lower bound (LB), the upper bound (UB), the computational time in seconds (Time) and the percentage gap (Gap) between the UB and LB values, returned by CPLEX. As in the previous tables, whenever an optimal solution is found, it is reported between the LB and UB columns.

No relevant information can be derived from the smallest instances with n = 25, since they are all optimally solved by both models in less than a second (see Table 4a). The results in Table 4b (referring to n = 50) show that Basic and BC do not solve to optimality the same subset of 14 instances. On these instances, the gap value of BC is smaller than the one of Basic in 11 out of 14 cases. In 6 of these cases (instances n°80, 81, 82, 95, 96 and 98) the gap difference is higher than 4%, while it is higher than 6% in 3 of these cases. In the 3 cases in which the gap of Basic is smaller, the difference is always lower than 2% (see instances n°97, 110 and 112). With respect to the computational time performances, we note that BC is faster than Basic for 29 out of the 31 instances that are solved to optimality by both approaches. In the two cases in which Basic is faster the difference is negligible, being smaller than 0.2

Table 4: Computational comparison between Basic and BC algorithms.

seconds. On the other hand, when BC is faster, the difference is greater than 3 seconds in 6 cases, and greater than 2 seconds in 10 cases. The peak for both

14

algorithms is instance n°83, that is solved in 139 seconds by Basic and in 46.3 seconds by BC.

15

From the results of Table 4c (n = 75), we note that 15 instances are solved to optimality by both models. In these cases, BC is always faster, often by a significant margin. Indeed, BC requires up to one fourth of the time required by Basic in 7 out of 15 cases, and up to one third in 9 cases. Moreover, both approaches find upper and lower bounds for the same 15 instances. For BC, the gap between upper and lower bounds is smaller than 5% in 11 cases, while it is smaller than 5% only in 4 cases for Basic. Finally, no feasible solution is found by either of the two approaches for the remaining 15 instances. For these instances, BC finds better lower bounds than Basic in 12 cases.

Finally, we comment the results for the instances with n = 100 (Table 4d). Both algorithms solve to optimality 15 instances. In these cases, BC requires less computational time than Basic 13 times. We observe in particular that BC is about 500 times faster for the instances n°189, and about 25 times faster for the instance n°193. In 5 cases, BC is at least twice faster than Basic. On the other hand, Basic is significantly faster only once (instance n°176).For the remaining 30 instances, Basic is able to find feasible solutions only twice (instances n°194 and 198), while BC finds feasible solutions in 5 additional cases (instances n°180, 183, 195, 196 and 197). Finally, considering the 23 instances for which both algorithms do not find feasible solutions, BC finds better lower bounds than Basic 17 times.

Overall, BC outperforms Basic significantly, being able to find more feasible solutions, and having in most cases either faster convergence times or better solution gaps when a time limit is reached.

6 Conclusions

In this work, we described a novel Branch-and-Cut approach to solve the MSTC problem. In particular, our main contribution is related to the proposal of a new set of valid inequalities, based on combined properties belonging to any feasible solution. Furthermore, we tested the approach we designed on the benchmark instances and compared it with a previous one. Our tests showed our approach to perform better on all instances except one, despite not using a preprocessing algorithm presented in the previous work in order to simplify the instances. Moreover, we created a new set of feasible instances, in order to test farther our approach and allow other researchers to have access to a wider set of benchmark instances for the problem. Future research will focus on finding new effective valid inequalities in order to improve our Branch-and-Cut approach.
